Analytical tractability is one of the challenges faced by many alternative models that try to generalize the Black-Scholes option pricing model to incorporate more empirical features. The aim of this paper is to extend the analytical tractability of the Black-Scholes model to alternative models with jumps. We demonstrate that a double exponential jump diffusion model can lead to an analytic approximation for finite-horizon American options (by extending the Barone-Adesi and Whaley method) and analytical solutions for popular path-dependent options (such as lookback, barrier, and perpetual American options). Numerical examples indicate that the formulae are easy to implement, and are accurate.

Key words: contingent claims; high peak; heavy tails; volatility smile; overshoot

History: Accepted by Ravi Jagannathan, finance; received December 3, 2002. This paper was with the authors 3 months for 2 revisions.

1. Introduction

Much research has been conducted to modify the Black-Scholes model based on Brownian motion and normal distribution in order to incorporate two empirical features: (1) The asymmetric leptokurtic features. In other words, the return distribution is skewed to the left, and has a higher peak and two heavier tails than those of the normal distribution. (2) The volatility smile. More precisely, if the Black-Scholes model is correct, then the implied volatility should be constant, but it is widely recognized that the implied volatility curve resembles a “smile,” meaning that it is a convex curve of the strike price.

To incorporate the asymmetric leptokurtic features in asset pricing, a variety of models have been proposed, including, among others, (a) chaos theory, fractal Brownian motion, and stable processes; (b) generalized hyperbolic models, including log t model and log hyperbolic model; and (c) time-changed Brownian motions, including log variance gamma model. In a parallel development, different models are also proposed to incorporate the “volatility smile” in option pricing. Popular ones are (a) stochastic volatility and GARCH models; (b) constant elasticity of variance (CEV) model; (c) normal jump diffusion models; (d) affine stochastic volatility and affine jump diffusion models; and (e) models based on Lévy processes. For the background of these alternative models, see, for example, Hull (2000) and Carr et al. (2003).

Unlike the original Black-Scholes model, although many alternative models can lead to analytic solutions for European call and put options, it is difficult to do so for path-dependent options, such as American options, lookback options, and barrier options. Even numerical methods for these derivatives are not easy. For example, the convergence rates of binomial trees and Monte Carlo simulation for path-dependent options are typically much slower than those for call and put options; for a survey, see, for example, Boyle et al. (1997).

This paper attempts to extend the analytical tractability of Black-Scholes analysis for the classical geometric Brownian motion to alternative models with jumps. In particular, we demonstrate that a double exponential jump diffusion model (Kou 2002) can lead to analytic approximation for finite-horizon American options by extending the approximation in Barone-Adesi and Whaley (1987) for the classical geometric Brownian motion model, and analytical solutions for lookback, barrier, and perpetual American options.

The paper is organized as follows. Section 2 gives a basic setting of the double exponential jump diffusion model, and presents intuition on why the analytical solutions are possible. An analytical approximation
of finite-time American options is given in §3, and the analysis of other path-dependent options is conducted in §4. The concluding remarks are given in §5. All the proofs are given in the appendices.

2. Background and Intuition

2.1. The Double Exponential Jump Diffusion Model

Under the double exponential jump diffusion model, the dynamics of the asset price $S(t)$ is given by

$$
\frac{dS(t)}{S(t-)} = \mu dt + \sigma dW(t) + d \left( \sum_{i=1}^{(N(t))} (V_i - 1) \right),
$$

where $W(t)$ is a standard Brownian motion, $N(t)$ a Poisson process with rate $\lambda$, and $\{V_i\}$ a sequence of independent identically distributed (i.i.d.) nonnegative random variables such that $Y = \log(V)$ has an asymmetric double exponential distribution with the density

$$f_Y(y) = p \cdot \eta_1 e^{-(y-\eta_2)} 1_{(y \geq 0)} + q \cdot \eta_2 e^{\eta_1 y} 1_{(y < 0)}, \quad \eta_1 > 1, \ \eta_2 > 0,$

where $p, q \geq 0, p + q = 1$. Here the condition $\eta_1 > 1$ is imposed to ensure that the asset price $S(t)$ has finite expectation. Note that the means of the two exponential distributions are $1/\eta_1$ and $1/\eta_2$, respectively. In the model, all sources of randomness, $N(t), W(t)$, and $Y$s, are assumed to be independent.

Because of the jumps, the risk-neutral probability measure is not unique. Following Lucas (1978) and Naik and Lee (1990), it can be shown (see, e.g., Kou 2002) that, by using the rational expectations argument with a HARA-type utility function for the representative agent, one can choose a particular risk-neutral measure so that the equilibrium price of an option is given by the expectation under this risk-neutral measure of the discounted option payoff. Under this risk-neutral probability measure, the asset price $S(t)$ still follows a double exponential jump diffusion process:

$$
\frac{dS(t)}{S(t-)} = (r - \lambda^* \xi^*) dt + \sigma dW^*(t) + d \left( \sum_{i=1}^{(N^*(t))} (V_i^* - 1) \right),
$$

with the return process $X(t) = \log(S(t)/S(0))$ given by

$$
X(t) = \left( r - \frac{1}{2} \sigma^2 - \lambda^* \xi^* \right) t + \sigma W^*(t) + \sum_{i=1}^{(N^*(t))} Y_i^*, \quad X(0) = 0.
$$

Here $W^*(t)$ is a standard Brownian motion under $P^*$, $\{N^*(t); t \geq 0\}$ is a Poisson process with intensity $\lambda^*, V^* = e^{\xi^*}$. The log jump sizes $\{Y_1^*, Y_2^*, \cdots \}$ still form a sequence of i.i.d. random variables with a new double exponential density $f_Y(y) \sim p^* \eta_1^* e^{-\eta_2^* y} 1_{(y \geq 0)} + q^* \eta_2^* e^{\eta_1^* y} 1_{(y < 0)}$. The constants $p^*, q^* \geq 0, p^* + q^* = 1, \lambda^* > 0, \eta_1^*, \eta_2^* > 0$, and

$$
\xi^* := \mathbb{E}[V^*] - 1 = \frac{p^* \eta_1^*}{\eta_1^* - 1} + \frac{q^* \eta_2^*}{\eta_2^* + 1} - 1
$$

all depend on the utility function of the representative agent. All sources of randomness, $N^*(t), W^*(t)$, and $Y^*$s, are still independent under $P^*$.

Since we focus on option pricing in this paper, to simplify the notation, we shall drop the superscript * in the parameters, i.e., using $p, q, \eta_1, \eta_2$ rather than $p^*, q^*, \eta_1^*, \eta_2^*$. The understanding is that all the processes and parameters below are under the risk-neutral probability measure $P^*$.

2.2. Intuition of the Pricing Formulae

Without the jump part, the model simply becomes the classical geometric Brownian motion model. Pricing formulae for American options, barrier options, and lookback options are all well known under the geometric Brownian motion model. With the jump part, however, it becomes very difficult to derive analytical solutions for these options.

The reason for that is as follows. To price American options, barrier options, and lookback options for general jump diffusion processes, it is crucial to study the first passage times that the process crosses a flat boundary with a level $b$. Without loss of generality, assume $b > 0$. When a jump diffusion process crosses the boundary, sometimes it hits the boundary exactly and sometimes it incurs an “overshoot” $X(\tau_b) - b$, over the boundary, where $\tau_b$ is the first time that the process $X(t)$ crosses the boundary. See Figure 1 for an illustration.

The overshoot presents several problems, if one wants to compute the distribution of the first passage times analytically. First, one needs the exact distribution of the overshoot, $X(\tau_b) - b$; particularly, $P[X(\tau_b) - b > x]$, $x > 0$. Second, one needs to know the dependence structure between the overshoot, $X(\tau_b) - b$, and the first passage time $\tau_b$. Both difficulties can be resolved under the assumption that the jump size $Y$ has an exponential type distribution; see Kou and Wang (2003). Finally, if one wants to use the reflection principle to study the first passage times, the dependence structure between the overshoot and the terminal value $X(t)$ is also needed.

Davydov and Linetsky (2001, 2003) provide analytical solutions for various path-dependent options under the CEV diffusion model.
If the jump size distribution is one sided, one can solve the overshoot problems\(^7\) by either using renewal equations or fluctuation identities for Lévy processes; see, e.g., Avram et al. (2001) and Rogers (2000). However, for two-sided jumps, because of the ladder-variable problems, generally speaking the renewal equations are not available and the fluctuation identities become too complicated for explicit computation; see, e.g., the discussion in Siegmund (1985) and Rogers (2000).

### 2.3. Some Notations
The moment-generating function of \(X(t)\) is given by \(E[e^{iX(t)}] = \exp[G(\theta)t]\), where the function \(G(\cdot)\) is defined as

\[
G(x) := x(r - \frac{1}{2} \sigma^2 - \lambda \xi) + \frac{1}{2} x^2 \sigma^2 + \lambda \left( \frac{p \eta_1}{\eta_1 - x} + \frac{q \eta_2}{\eta_2 + x} - 1 \right).
\]

Lemma 3.1 in Kou and Wang (2003) shows that the equation \(G(x) = x, \forall x > 0\), has exactly four roots: \(\beta_{1,a}, \beta_{2,a}, -\beta_{3,a}\), and \(-\beta_{4,a}\), where

\[
0 < \beta_{1,a} < \eta_1 < \beta_{2,a} < \infty, \quad 0 < \beta_{3,a} < \eta_2 < \beta_{4,a} < \infty.
\]

To use the Itô formula for jump processes, we also need the infinitesimal generator of \(X(t)\):

\[
(\mathcal{L}V)(x) := \frac{1}{2} \sigma^2 V''(x) + (r - \frac{1}{2} \sigma^2 - \lambda \xi) V'(x) + \lambda \int_{-\infty}^{\infty} [V(x + y) - V(x)] f_\gamma(y) \, dy.
\]

### 3. Pricing Finite Time Horizon American Options
Most of call and put options traded in the exchanges in both the United States and Europe are American-type options. Therefore, it is of great interest to calculate the prices of American options accurately and quickly. The price of a finite-horizon American option is the solution of a finite-horizon free boundary problem. Even within the classical geometric Brownian motion model, except in the case of the American call options.
option with no dividend, there is no analytical solution available.\textsuperscript{8}

To price American options under general jump diffusion models, one may consider numerically solving the free boundary problems via lattice or differential equation methods; see, e.g., Amin (1993), Zhang (1997), d’Halluin et al. (2003). Extending the Barone-Adesi and Whaley (1987) approximation for the classical geometric Brownian motion model, we shall consider an alternative approach that takes into consideration the special structure of the double exponential jump diffusions. One motivation for such an extension is its simplicity, as it yields an analytic approximation that only involves the price of a European option. Our numerical results in Tables 1 and 2 suggest that the approximation error is typically less than 2\%, which is less than the typical bid-ask spread (about 5\% to 10\%) for American options in exchanges. Therefore, the approximation can serve as an easy way to get a quick estimate that is perhaps accurate enough for many practical situations.

The extension of Barone-Adesi and Whaley’s (1987) method works nicely for double exponential jump diffusion models mainly because explicit solutions are available to a class of relevant integro-differential free boundary problems; see Equations (A3) and (A4) in Appendix A. We want to point out that there exist other more elaborate but more accurate approximations (such as Broadie and Detemple 1996, Carr 1998, and Ju 1998) for geometric Brownian motion models, and whether these algorithms can be effectively extended to jump diffusion models invites further investigation.

To simplify notation, we shall focus only on the finite-horizon American put option without dividends, as the methodology is also valid for the finite-horizon American call option with dividends. The analytic approximation involves two quantities: \( \text{EuP}(v, t) \), which denotes the price of a European put option with initial stock price \( v \) and maturity \( t \), and \( \text{P}^*[S(t) \leq K] \), which is the probability that the stock price at the maturity \( t \) is below \( K \) with initial stock price \( v \). Both \( \text{EuP}(v, t) \) and \( \text{P}^*[S(t) \leq K] \) can be computed fast by using either the closed-form solutions in Kou (2002) or the Laplace transforms in Kou et al. (2003).

We need some notations. Let \( z = 1 - e^{-rt}, \beta_1 \equiv \beta_1(t/z), \beta_4 \equiv \beta_4(t/z), C_\beta = \beta_3 \beta_4 (1 + \eta_2), D_\beta = \eta_2 (1 + \beta_3) (1 + \beta_4) \), in the notation of Equation (4). Define \( v_0 \equiv v_0(t) \in (0, K) \) as the unique solution\textsuperscript{9} to the equation

\[
C_\beta K - D_\beta [v_0 + \text{EuP}(v_0, t)] = (C_\beta - D_\beta) Ke^{-rt} \cdot \text{P}^*[S(t) \leq K].
\]

Note that the left-hand side of (6) is a strictly decreasing function of \( v_0 \) (because \( v_0 + \text{EuP}(v_0, t) = e^{-rt} E^{[\max(S(t), K) | S(0) = v_0]} \)), and the right-hand side of (6) is a strictly increasing function of \( v_0 \) (because \( C_\beta - D_\beta = \beta_3 \beta_4 - \eta_2 (1 + \beta_3 + \beta_4) < 0 \)). Therefore, \( v_0 \) can be obtained easily by using, for example, the bisection method.

**Approximation.** The price of a finite-horizon American put option with maturity \( t \) and strike \( K \) can be approximated by \( \psi(S(0), t) \), where the value function \( \psi \) is given by

\[
\psi(v, t) = \begin{cases} 
\text{EuP}(v, t) + A e^{-\beta_1 t} + B e^{-\beta_2 t}, & \text{if } v \geq v_0 \\
K - v, & \text{if } v < v_0 
\end{cases}
\]

with \( v_0 \) being the unique root of Equation (6) and the two constants \( A \) and \( B \) given by

\[
A = \frac{v_0^{\beta_3}}{\beta_3 - \beta_4} \left\{ \beta_4 K - (1 + \beta_3) [v_0 + \text{EuP}(v_0, t)] + Ke^{-rt} \cdot \text{P}^*[S(t) \leq K] \right\} > 0, \quad (8)
\]

\[
B = \frac{v_0^{\beta_4}}{\beta_3 - \beta_4} \left\{ \beta_3 K - (1 + \beta_4) [v_0 + \text{EuP}(v_0, t)] + Ke^{-rt} \cdot \text{P}^*[S(t) \leq K] \right\} > 0. \quad (9)
\]

Tables 1 and 2 present numerical results for finite-horizon American put options, corresponding to \( t = 0.25 \) and \( t = 1.0 \) years. The parameters used here are \( S(0) = 100, \ p = 0.5, \) and \( r = 0.05 \). To save space, the numerical results for \( t = 0.5 \) and \( t = 1.5 \) are omitted, but they can be obtained from the authors upon request. We choose this set of maturities because most of the American options traded in exchanges have maturities between three months and one year. The “true” value is calculated by using the enhanced binomial tree method as in Amin (1993) with 1,600 steps (to ensure that the accuracy is up to about a penny) and the two-point Richardson extrapolation for the square-root convergence rate.

In the tables the maximum relative error is only about 2.6\%, while in most cases the relative errors are below 1\%. Note also the approximation tends to works better for small maturity \( t \); this is because of Assumption (A2) in the approximation, as will be explained in Appendix A.I. All the calculations are conducted on a Pentium 1500 PC. The approximation runs very fast, taking only about 0.04 second to

\textsuperscript{9} In Appendix A, we give a better upper bound in (A6) for \( v_0 \), that is \( K > v_0 + \text{EuP}(v_0, t) \).
compute one price, irrespective of the parameter ranges, while the lattice method works much slower, taking over one hour to compute one price.

4. Pricing Other Path-Dependent Options

Lookback and barrier options are among the most popular path-dependent options traded in exchanges worldwide, and in over-the-counter markets; perpetual American options are interesting because they serve as simple examples to illustrate finance theory.\(^{10}\)

We shall demonstrate in this section that in the double

---

\(^{10}\)Pricing of barrier, lookback, and perpetual American options also arises quite often in other contexts. For example, Merton (1974), Black and Cox (1976), and more recently Leland (1994), Longstaff (1995), Longstaff and Schwartz (1995), among others, use lookback and barrier options to value debt and contingent

4.1. Lookback Options
Because the calculation for the lookback call option follows just by symmetry, we will only provide the result for the lookback put option, whose price is given by

$$LP(T) = E^*[e^{-rT}\left(\max_{0 \leq s \leq T} M, \max_{0 \leq s \leq T} S(t)\right) - S(T)]$$

$$= E^*[e^{-rT}\left(\max_{0 \leq s \leq T} M, \max_{0 \leq s \leq T} S(t)\right)] - S(0),$$
where \( M \geq S(0) \) is a fixed constant representing the prefixed maximum at time 0.

**Theorem 1.** Using the notations \( \beta_{1, a+t} \) and \( \beta_{2, a+t} \) as in (4), the Laplace transform of the lookback put is given by

\[
\int_0^\infty e^{-\alpha T} LP(T) dT = \frac{S(0)A_a}{C_a} \left( \frac{S(0)}{M} \right)^{\beta_{1, a+t} - 1} + \frac{S(0)B_a}{C_a} \left( \frac{S(0)}{M} \right)^{\beta_{2, a+t} - 1} + \frac{M}{\alpha + r} - \frac{S(0)}{\alpha}
\]

for all \( \alpha > 0 \); here

\[
A_a = \frac{(\eta_1 - \beta_{1, a+t}) \beta_{2, a+t}}{\beta_{1, a+t} - 1}, \quad B_a = \frac{(\beta_{2, a+t} - \eta_1) \beta_{1, a+t}}{\beta_{2, a+t} - 1}, \quad C_a = (\alpha + r) \eta_1 (\beta_{2, a+t} - \beta_{1, a+t}).
\]

The proof of Theorem 1 will be given in Appendix B.1. Essentially, the proof explores a link between the Laplace transform of the lookback option and the Laplace transform of the first passage times of the double exponential jump diffusion process as solved explicitly in Kou and Wang (2003).

### 4.2. Barrier Options

There are eight types of (one dimensional, single) barrier options: up (down)-and-in (out) call (put) options. For example, the price of a down-and-out put (DOP) option is given by \( \text{DOP} = E[e^{-rT} (K - S(T))^+ \mathbf{1}_{\{\text{min}_{t \geq 0} S(t) \geq H\}}] \), where \( H < S(0) \) is the barrier level. Since all the eight types of barrier options can be solved in similar ways, we shall only illustrate with the up-and-in call (UIC) option, whose price is given by

\[
\text{UIC} = E[e^{-rT} (S(T) - K)^+ \mathbf{1}_{\{\max_{t \geq 0} S(t) \geq H\}}],
\]

where \( H > S(0) \) is the barrier level. Introduce the following notation: For any given probability \( \mathbb{P} \),

\[
\Psi(\mu, \sigma, \lambda, p, \eta_1, \eta_2; a, b, T) := \mathbb{P}[Z(T) \geq a, \max_{0 \leq t \leq T} Z(t) \geq b],
\]

where under \( \mathbb{P}, Z(t) \) is a double exponential jump diffusion process with drift \( \mu \), volatility \( \sigma \), and jump rate \( \lambda \), i.e., \( Z(t) = \mu t + \sigma W(t) + \sum_{i=1}^{N(t)} Y_i \), and \( Y \) has a double exponential distribution with density \( f_z(y) = p \cdot \eta_1 e^{-\eta_1 y} \mathbf{1}_{[y \geq 0]} + q \cdot \eta_2 e^{\eta_2 y} \mathbf{1}_{[y < 0]} \). The formula of the UIC option will be written in terms of \( \Psi \). The Laplace transforms of \( \Psi \) is computed explicitly in Kou and Wang (2003).

**Theorem 2.** The price of the UIC option is obtained as

\[
\text{UIC} = S(0) \Psi \left( r + \frac{1}{2} \sigma^2 - \lambda \xi, \sigma, \tilde{\lambda}, \tilde{p}, \tilde{\eta}_1, \tilde{\eta}_2; \right)
\]

\[
\log \left( \frac{K}{S(0)} \right), \log \left( \frac{H}{S(0)} \right), T \right)
\]

\[-Ke^{-rT} \frac{(\eta_1/(\eta_1 - 1)) \cdot (\eta_1/(\eta_1 - 1))}{(\eta_1/(\eta_1 - 1)) \cdot (\eta_1/(\eta_1 - 1))}, \tilde{\eta}_1 = \eta_1 - 1, \tilde{\eta}_2 = \eta_2 + 1, \tilde{\lambda} = \lambda(\xi + 1), \text{with } \xi \text{ given in (3) and } \Psi \text{ in (10)}. \]

The proof of Theorem 2 will be given in Appendix B.2. It uses a change of numeraire argument, which intuitively changes the unit of the money from the money market account to the underlying asset \( S(t) \), to reduce the computation of the expectation to the difference of two probabilities. For further background of the change of numeraire argument for jump diffusion processes, see, for example, Schröder (1999).

### 4.3. Numerical Results for Barrier and Lookback Options

Since the solutions for barrier and lookback options are given in terms of Laplace transforms, numerical inversion of Laplace transforms becomes necessary. To do this, we shall use the Gaver-Stehfest algorithm. Given the Laplace transform function \( \hat{f}(a) = \int_0^\infty e^{-at} f(x) dx \) of a function \( f(x) \), the algorithm generates a sequence \( f_n(x) \) such that \( f_n(x) \to f(x), n \to \infty \). The algorithm converges very fast; as we will see, it typically converges nicely even for \( n \) between 5 and 10. Kou and Wang (2003) report the details of implementation.

As a numerical illustration, we calculate both the lookback put option and the UIC barrier option in Table 3. For the lookback put option the predetermined maximum is \( M = 110 \); for the UIC option the barrier and the strike price are given by \( H = 120 \) and \( K = 100 \). The expiration dates for both options are the same: \( T = 1 \). The risk-free rate is \( r = 5\% \). The parameters used in the double exponential jump diffusion are \( \sigma = 0.2, p = 0.3, 1/\eta_1 = 0.02, 1/\eta_2 = \ldots \)

11The main advantages of the Gaver-Stehfest algorithm are: simplicity (a very short code will do the job), fast convergence, and good stability (i.e., the final output is not sensitive to a small perturbation of initial input). The main disadvantage is that it needs high accuracy computation, because it involves calculation of some factorial terms; typically 30–80 digit accuracy is needed. However, in many software packages (e.g., "Mathematica") one can specify arbitrary accuracy, and standard subroutines for high precision calculation in various programming languages (e.g., C++) are readily available.
0.04, \( \lambda = 3 \), \( S(0) = 100 \). To make a comparison with the limiting geometric Brownian motion model (\( \lambda = 0 \)), we also use \( \lambda = 0.01 \). The results are given in Table 3. All the computations are done on a Pentium 700 PC.

The simulation results from the standard Monte Carlo, along with the number of discretization points used, are also reported in the table. Note that the Monte Carlo simulation has two sources of errors: the random sampling error, and the systematic discretization bias. It is quite possible to significantly reduce the random sampling error here (thus the width of the confidence intervals) by using some variance reduction techniques, such as control variates and importance sampling. However, it is difficult to reduce the systematic discretization bias, resulting from approximating the maximum of a continuous time process by the maximum of a discrete time process in simulation.\(^\text{12}\) For both the lookback put and the UIC, it makes the calculation from the simulation biased low. Even in the Brownian motion case, because of the presence of boundary, this type of discretization bias is significant, resulting in a surprisingly slow rate of convergence\(^\text{13}\) in simulating the first passage time, both theoretically and numerically. Here, the standard Monte Carlo is used mainly because we focus on analytical solutions; for more efficient simulation methods, see the recent paper by Metwally and Atiya (2002), which proposes two schemes that reduce the discretization bias in Monte Carlo pricing of barrier options under jump diffusion models.

### 4.4. Perpetual American Options

To simplify the derivation, we shall only focus on the perpetual American put option, because the methodology is also valid for the perpetual American call option with dividends. Under the jump diffusion model, the price of an American put option is given by

\[
\psi(S(0)) = \sup_{\tau} E^*[e^{-r\tau}(K - S(\tau))^+] = \sup_{\tau} E^*[e^{-r\tau}(K - S(0)e^{X(\tau)})^+],
\]

where the supremum is taken over all stopping times \( \tau \) taking values in \([0, \infty]\).

**Theorem 3.** Using\(^\text{14}\) the notations \( \beta_{3, r} \) and \( \beta_{4, r} \) as in (4), the value\(^\text{15}\) of the perpetual American put option is given by \( \psi(S(0)) = V(S(0)) \), where the value function \( V \) is given by

\[
V(v) = \begin{cases} 
K - v, & \text{if } v < v_0, \\
Av^{-\beta_{3, r}} + Bv^{-\beta_{4, r}}, & \text{if } v \geq v_0,
\end{cases}
\]

\(^{12}\) Based on “sharp large deviation” for diffusion models, Baldi et al. (1999) suggest a simulation method for pricing of barrier and lookback options; it remains to be seen whether the method can be effectively generalized to simulate models with jumps.

\(^{13}\) Asmussen et al. (1995) show that, theoretically, the discretization error has an order 1/2, which is much slower than the order 1 convergence for simulation without the boundary; 16,000 points are suggested in the paper for a Brownian motion with drift \(-1\) and volatility \( \sigma = 1 \) and time \( T = 8 \).

\(^{14}\) Gerber and Shiu (1998) and Mordecki (1999) study the same optimal stopping problem with one-sided jumps (can only jump up or down); this may not have the overshoot problem if the process always jumps away from (not jump towards) the boundary. Also \( r = 0 \) in Mordecki (1999). Here we focus on the (two-sided) double exponential jump diffusion processes with \( r \geq 0 \).
Figure 2  Values of American Put Options

where

\[ v_0 = K \frac{\eta_2 + 1}{\eta_2} \cdot \frac{\beta_{3_r} + \beta_{4_r}}{1 + \beta_{3_r} + \beta_{4_r}}, \]
\[ A = v_0^{\beta_{4_r}} \cdot 1 + \frac{1 + \beta_{3_r}}{\beta_{4_r} - \beta_{3_r}} \left[ \frac{v_0 - \beta_{3_r}}{1 + \beta_{3_r}} - K \right] > 0, \]
\[ B = v_0^{\beta_{3_r}} \cdot 1 + \frac{1 + \beta_{3_r}}{\beta_{4_r} - \beta_{3_r}} \left[ \frac{v_0 - \beta_{3_r}}{1 + \beta_{3_r}} - K \right] > 0. \]

Furthermore, the optimal stopping time is given by \( \tau^* = \inf\{t \geq 0 : S(t) \leq v_0 \}. ^{16} \]

The proof \(^{16}\) will be given in Appendix B.3. Note that the solution given in (12) satisfies the smooth-fit principle (i.e., the value function is continuous and continuously differentiable across the free boundary \( v_0 \)). ^{17}

Figure 2 graphs of the value of a perpetual American put option versus its parameters, \( S(0), \eta_1, \eta_2, p, \lambda \). The defaulting parameters are \( r = 0.06, \sigma = 0.20, K = 100, S(0) = 100, \lambda = 3, p = 0.3, 1/\eta_1 = 0.02, \) and \( 1/\eta_2 = 0.03 \). It only takes less than one second to generate all the pictures in Figure 2 on a Pentium 700 PC. Not surprisingly, Figure 2 indicates that the option value is a decreasing function of \( S(0), p \), and is an increasing function of \( \lambda, 1/\eta_2 \), and \( \sigma \), as it is a put option. What is interesting is that the option value is an increasing function of \( 1/\eta_1 \), which is the mean of the positive jumps. The reason is that the risk-neutral drift also depends on \( \eta_1 \); a similar phenomenon was also pointed out in Merton (1976).

5. Concluding Remarks

Both the normal jump diffusion model and the double exponential jump diffusion model are special cases

\(^{16}\) A result similar to (12) is also independently obtained by Mordecki (2002). However, there are two key differences. First, our proof not only covers the case of the perpetual American options, but also solves another infinite-horizon free boundary problem (with a more complicated boundary condition) of (A3) and (A4), arising in approximating the finite-horizon American options; see Appendix A.1. Second, the proof in Mordecki (2002) shows the results indirectly, as it first derives some general representations for Lévy processes, and then shows that the representations can be computed explicitly if the jump sizes are exponentially distributed. Here we prove and calculate the result directly by using martingale and PDE methods, without appealing to more general results from Lévy processes.

\(^{17}\) The smooth-fit principle may not hold for general Lévy processes; see Pham (1997) and Boyarchenko and Levendorski (2002a), where sufficient conditions for the smooth-fit principle are given.
of the affine jump diffusion models (Duffie et al. 2000, Chacko and Das 2002), which include stochastic volatility and jumps in the volatility, and of Lévy processes, which have independent increments but with more general distributions. Whether the double exponential jump diffusion model is suitable for modeling purposes is ultimately a choice between analytical tractability and reality, and it should be judged on a case-by-case basis. (For example, the independent increment assumption is perhaps more defensible in the case of currency markets than in the case of equity markets.) See Cont and Tankov (2002) for calibration of the double exponential jump diffusion model to market data, and some empirical comparison with other models.

It is worth mentioning that jump diffusion models may also be useful in modeling credit risks. In fact, Huang and Huang (2003) have used the double exponential jump diffusion model to study credit spread, and the empirical results there seem to be promising.

From a broader perspective, the paper calls for consideration of using exponential type distributions in modeling jumps in asset pricing, and, by understanding the simplest cases first, the results may hopefully shed some light on more general models with jumps.

Acknowledgments
The authors thank an anonymous referee, the associate editor, and the editor for many helpful comments. We are also grateful to many people who offered insights into this work, including seminar participants at various universities, and conference participants at Risk Annual Boston Meeting 2000, UCLA Mathematical Finance Conference 2001, Taipei International Quantitative Finance Conference 2001, Fifth SIAM Conference on Control and Its Applications 2001, American Finance Association Annual Meeting 2001, and the 11th Derivatives Conference in New York City 2003. We would like to thank Giovanni Petrella for his assistance in computing the numerical values of American options. All errors are ours alone.

Appendix A. Derivation of Approximation (7)

A.1. Outline of the Main Steps in the Derivation
Let $t$ be the remaining time to maturity. Suppose the optimal exercise boundary is $v_0(t)$; in other words, it is optimal to exercise the option whenever the stock price falls below $v_0(t)$. Letting $x_0(t) = \log(v_0(t))$, $x = \log(v)$, and using the generator $\mathcal{D}$ in (5), the value function $V(x, t) = \psi(x, t)$ and the optimal exercise boundary $v_0(t)$ must satisfy the free boundary problem: $-\mathcal{D}V + rV = 0$, for $x > x_0(t)$; and $V(x, t) = K - e^x$, for $x < x_0(t)$. Define the early exercise premium as $\epsilon(x, t) := V(x, t) - \text{EuP}(e^x, t)$. Since the European put price satisfies the equation $-\text{EuP}' + r\text{EuP} + \mathcal{D}\text{EuP} = 0$, for all $t$, it follows that the early exercise premium satisfies the equation

$$\epsilon(x, t) = K - e^x - \text{EuP}(e^x, t), \quad \forall x \leq x_0(t). \quad (A1)$$

Introduce the change of variable $z = 1 - e^{-r t}$, $g(x, z) = e(x, t)/z$. It is easy to see that $z_t = r e^{-r t}$, $z_x = z g_x$, $e_x = z g_x$, $e_t = z g_z + g_x g_z$. Plugging this back into (A1), and dividing $z$ on both sides, we have

$$-r(z - 1)g_z - \left(\frac{r}{z} + \lambda\right)g + \frac{1}{2} \sigma^2 g_{xx} + \left(r - \frac{1}{2} \sigma^2 - \lambda \xi\right)g_x + \lambda \int_{-\infty}^{\infty} g(x + y, z) f(y) dy = 0$$

for all $x > x_0(t)$ and $g(x, z) = (1/z)(K - e^x - \text{EuP}(e^x, t))$, $\forall x \leq x_0(t)$. Following Barone-Adesi and Whaley (1987), the approximation will set

$$(1 - z)g_z \approx 0. \quad (A2)$$

This is a reasonable assumption especially for very big or very small $t$. Indeed, as $t \to 0$, $1 - z \to 0$, while as $t \to \infty$, $g_z \to 0$, because $g(x, z$) converges to the price of a perpetual American put option. This also explains why, in the numerical tables, the error tends to be larger when $t = 1$.

With Approximation (A2), the function $g$ satisfies the following equations:

$$-\left(\frac{r}{z} + \lambda\right)g + \frac{1}{2} \sigma^2 g_{xx} + \left(r - \frac{1}{2} \sigma^2 - \lambda \xi\right)g_x + \lambda \int_{-\infty}^{\infty} g(x + y, z) f(y) dy = 0, \quad \forall x > x_0(t) \quad (A3)$$

and

$$g(x, z) = \frac{1}{z}(K - e^x - \text{EuP}(e^x, t)), \quad \forall x \leq x_0(t). \quad (A4)$$

If we regard $t$, and hence $z$ and $x_0(t)$, to be fixed, (A3) becomes an ordinary integro-differential equation with free-boundary $x_0(t)$. Note that the boundary condition in (A4) involves the European put option price $\text{EuP}(e^x, t)$, which makes solving the free boundary problem more difficult than that for perpetual American options. Under the assumption of exponential jump size distribution, however, the above free boundary problem can be solved explicitly as in Appendix A.2, resulting in the approximation in (7).

A.2. Solving the Free Boundary Problems (A3) and (A4)

**Lemma 1.** Define

$$\tilde{V}(x) = \begin{cases} K - e^x - h(x), & \text{if } x < x_0 \text{, } \\ A e^{-\beta x} + Be^{-\beta_4}, & \text{if } x \geq x_0, \end{cases}$$

where $\beta_3, \beta_4 > 0$, $x_0 \in (-\infty, \infty)$ are arbitrary constants, and $h(x)$ arbitrary continuous function. Then for any constant $b$, we have for all $x > x_0$,

$$-\beta \tilde{V} + \mathcal{D} \tilde{V}(x) = \begin{cases} A e^{-\beta_3} \tilde{f}(\beta_3) + Be^{-\beta_4} \tilde{f}(\beta_4) + \lambda \eta_2 e^{(x-x_0)/\eta_2} \left[ K \frac{e^{u_0}}{\eta_2} + A e^{-\beta x} + Be^{-\beta_4} \right] - \int_{-\infty}^{0} h(x+y)e^{\eta_1 y} dy, & \text{if } x > x_0, \end{cases}$$

where $\tilde{f}(x) := G(-x) - b$. 

\[ g(x, z) = \frac{1}{z}(K - e^x - \text{EuP}(e^x, t)), \quad \forall x \leq x_0(t). \]
Proof. First, we want to compute \( \int_{-\infty}^{\infty} \tilde{V}(x+y)dF(y) \), which is essential to compute the generator \( (\tilde{\mathcal{L}}\tilde{V})(x) \). For \( x > x_0 \), we have

\[
\begin{align*}
\int_{-\infty}^{\infty} \tilde{V}(x+y)dF(y) & = \int_{-\infty}^{x_0-x} (K - e^{\gamma x} - h(x+y))q_\eta e^{\gamma y} dy \\
& \quad + \int_{x_0-x}^{0} (Ae^{-\beta_1 y} + Be^{-\beta_2 y}) q_\eta e^{\gamma y} dy \\
& \quad + \int_{0}^{\infty} (Ae^{-\beta_1 y} + Be^{-\beta_2 y})P_\eta e^{-\gamma y} dy \\
& = q e^{(x_0-x)\eta} \left[ \frac{K - \eta e^{\gamma y}}{1 + \eta_2} + \frac{A}{\eta_2 - \beta_3} e^{-\beta_3 y} + \frac{B}{\eta_1 + \beta_4} \right] \\
& \quad - \int_{-\infty}^{x_0-x} h(x+y)q_\eta e^{\gamma y} dy \\
& \quad + \frac{q_\eta B}{\eta_2 - \beta_3} [e^{-\beta_3 y} - e^{-\beta_2 y}, e^{(x_0-x)\eta}] \\
& \quad + \left[ A \frac{\eta_1 e^{-\beta_3 y}}{\eta_1 + \beta_4} + B \frac{\eta_1 e^{-\beta_4 y}}{\eta_1 + \beta_4} \right].
\end{align*}
\]

Next, for \( x > x_0 \), we have

\[
\int_{-\infty}^{\infty} \tilde{V}(x+y)dF(y) = \frac{1}{2} \sigma^2 (A e^{-\beta_1 y} + B e^{-\beta_2 y}) + (r - \frac{1}{2} \sigma^2 - \lambda \gamma) (A e^{-\beta_1 y} + B e^{-\beta_2 y}) - b (A e^{-\beta_1 y} + B e^{-\beta_2 y}) - \lambda (A e^{-\beta_1 y} + B e^{-\beta_2 y}) + \frac{\lambda}{2} [q e^{(x_0-x)\eta} \left[ \frac{K - \eta e^{\gamma y}}{1 + \eta_2} + \frac{A}{\eta_2 - \beta_3} e^{-\beta_3 y} + \frac{B}{\eta_1 + \beta_4} \right] \\
& \quad - \int_{-\infty}^{x_0-x} h(x+y)q_\eta e^{\gamma y} dy \\
& \quad + \frac{q_\eta B}{\eta_2 - \beta_3} [e^{-\beta_3 y} - e^{-\beta_2 y}, e^{(x_0-x)\eta}] \\
& \quad + \left[ A \frac{\eta_1 e^{-\beta_3 y}}{\eta_1 + \beta_4} + B \frac{\eta_1 e^{-\beta_4 y}}{\eta_1 + \beta_4} \right].
\]

from which the proof is terminated. \( \square \)

**Lemma 2.** For every \( x_0 \), we have

\[
\begin{align*}
\frac{d}{dx} \text{EuP}(e^t, t) & = \text{EuP}(e^{t_0}, t) - Ke^{-rt} \mathbb{P}(S(t) \leq K | S(0) = e^{t_0}) \\
\int_{-\infty}^{0} \text{EuP}(e^{t_0+y}, t)e^{\eta_2 y} dy & = \frac{1}{\eta_2 + 1} \text{EuP}(e^{t_0}, t) + \frac{Ke^{-rt}}{\eta_2 (\eta_2 + 1)} \mathbb{P}(S(t) \leq K | S(0) = e^{t_0}) \\
& \quad + \frac{Ke^{-rt}}{\eta_2 (\eta_2 + 1)} E \left[ \left( \frac{S(t)}{K} \right)^{\eta_2} \mathbb{1}_{[S(t) > K]} | S(0) = e^{t_0} \right].
\end{align*}
\]

**Proof.** We have

\[
\begin{align*}
\text{EuP}(e^t, t) & = \mathbb{E}^* \left[ e^{-rt} (K - e^{\gamma X(t)})^+ \right] = \mathbb{E}^* \int_{-\infty}^{\infty} e^{-rt} 1_{[y \geq 0]} dy \\
& = \mathbb{E}^* \int_{-\infty}^{0} e^{-rt} e^{\gamma X(t)} 1_{[K - \xi_0 X(t) \geq 0]} dz \\
& = \int_{-\infty}^{0} \mathbb{E}^* \left[ e^{-rt} e^{\gamma X(t)} 1_{[K - \xi_0 X(t) \geq 0]} \right] dz.
\end{align*}
\]

Hence

\[
\frac{d}{dt} \text{EuP}(e^t, t) = \mathbb{E}^* \left[ e^{-rt} e^{\gamma X(t)} 1_{[K - \xi_0 X(t) \geq 0]} \right].
\]

from which the first equation follows readily. As for the second equation, we have

\[
\begin{align*}
\int_{-\infty}^{0} \text{EuP}(e^{t_0+y}, t)e^{\eta_2 y} dy & = \mathbb{E}^* \int_{-\infty}^{0} e^{-rt} (K - e^{\gamma X(t)})^+ e^{\eta_2 y} dy \\
& = e^{-rt} \mathbb{E}^* \int_{-\infty}^{0} 1_{[K - \xi_0 X(t) \geq 0]} e^{\eta_2 y} (K - e^{\gamma X(t)}) dy \\
& \quad + e^{-rt} \mathbb{E}^* \int_{-\infty}^{\log(K/e^{t_0})} 1_{[K - \xi_0 X(t) < 0]} e^{\eta_2 y} (K - e^{\gamma X(t)}) dy \\
& = e^{-rt} \mathbb{E}^* \left[ \frac{K}{\eta_2} - \frac{S(t)}{\eta_2 + 1} \right] 1_{[K(S(t)) \geq 0]} \\
& \quad + \frac{K}{\eta_2 + 1} \cdot e^{-rt} \mathbb{E}^* \left[ (S(t) - \xi_0) 1_{[K(S(t)) \geq 0]} \right],
\end{align*}
\]

from which the conclusion follows. \( \square \)

Now we are in a position to solve the free boundary problem of (A3) and (A4). Since \( \varepsilon(x, t) = z_0(x, t) \), it is not difficult to see that (A3)-(A4) reduce to \( -(r + \gamma) = 0 \), \( \forall x > x_0(t) \), \( \varepsilon(x, t) = e^{-t} - \text{EuP}(e^t, t), \forall x \leq x_0(t) \). Note we regard \( t \) as fixed. Denote \( x_0 = x_0(t) \). By Lemma 1, for \( \varepsilon = e^{-t} + Be^{-\beta_2 y} \) with \( x > x_0 \), we must have \( G(-\beta_3) - r/z = 0 \), \( G(-\beta_4) - r/z = 0 \), and

\[
\frac{K}{\eta_2 - \beta_3} = \int_{-\infty}^{0} \text{EuP}(e^{t_0+y}, t)e^{\eta_2 y} dy.
\]

The smooth-fit principle (i.e., the value function is continuous and continuously differentiable across the free boundary) yields two more equations \( K - e^{t_0} = e^{t_0} - \text{EuP}(e^{t_0}, t) = A e^{-\beta_0 y} + Be^{-\beta_4 y}, e^{t_0} + (\partial \varepsilon \partial x) \text{EuP}(e^t, t)|_{x = x_0} = A \beta_0 e^{-\beta_0 y} + B \beta_4 e^{-\beta_4 y} \). These five equations determine the five unknown parameters \( A, B, x_0, \beta_0, \beta_4 \). It is not difficult to verify that \( A \) and \( B \) are given by

\[
A = e^{t_0} \frac{1}{\beta_4 - \beta_3} \left[ B_4(K - e^{t_0} - \text{EuP}(e^{t_0}, t)) \right.
\]

\[
\left. - \left( e^{t_0} + \frac{\delta}{\delta x} \text{EuP}(e^t, t) \right) \right|_{x = x_0},
\]

\[
B = e^{t_0} \frac{1}{\beta_3 - \beta_4} \left[ B_4(K - e^{t_0} - \text{EuP}(e^{t_0}, t)) \right.
\]

\[
\left. - \left( e^{t_0} + \frac{\delta}{\delta x} \text{EuP}(e^t, t) \right) \right|_{x = x_0}.
\]

\]
After some algebra, (A5) yields that the free boundary \( x_0 \) must satisfy the equation:

\[
\frac{\beta_3 \beta_2 K - e^{x_0} \beta_3 + \beta_4 + 1 + \beta_4 \beta_3}{\eta_2} = \frac{\partial}{\partial x} \text{Eup}(e^{x}, t) \bigg|_{x=x_0} + (\beta_4 + \beta_4 - \eta_2) \text{EuP}(e^{x_0}, t) + (\eta_2 - \beta_4)(\eta_2 - \beta_3) \int_{-\infty}^{0} \text{EuP}(e^{x+y}, t) \cdot e^{y} dy.
\]

Using Lemma 2, we have

\[
A = \frac{e^{\beta_3 x_0}}{\beta_4 - \beta_3} \left[ \beta_4 K - (1 + \beta_4)[e^{x_0} + \text{EuP}(e^{x_0}, t)] + Ke^{-rt} \text{P}^*[S(t) \leq K | S(0) = e^{x_0}] \right],
\]

\[
B = \frac{e^{\beta_3 x_0}}{\beta_3 - \beta_4} \left[ \beta_4 K - (1 + \beta_4)[e^{x_0} + \text{EuP}(e^{x_0}, t)] + Ke^{-rt} \text{P}^*[S(t) \leq K | S(0) = e^{x_0}] \right],
\]

which are exactly (8) and (9). Again using Lemma 2, we have

\[
\frac{\beta_3 \beta_2 K - e^{x_0} (1 + \beta_4)(1 + \beta_4)}{\eta_2} = \text{Eup}(e^{x_0}, t) \left[ \frac{(1 + \beta_4)(1 + \beta_4)}{\eta_2 + 1} \right] + \frac{\beta_3 \beta_2 - \beta_3 \beta_4}{\eta_2 + 1} + (\eta_2 - \beta_4)(\eta_2 - \beta_3) \cdot Ke^{-rt} \text{P}^*[S(t) \leq K | S(0) = e^{x_0}] + \frac{Ke^{-rt} \text{P}^*[S(t) \leq K | S(0) = e^{x_0}]}{\eta_2 + 1}.
\]

Since \( \eta_2 \) is typically very large, as \( 1/\eta_2 \) is about 2 to 10%, the last term in the above equation is generally very small, because the expectation \( \text{E}^*[S(t)/K]^{-\eta_2} | S(t) \geq K | S(0) = e^{x_0} \) is typically small. Ignoring the last term, we have that \( x_0 \) must satisfy the equation

\[
\frac{\beta_3 \beta_2 K - e^{x_0} (1 + \beta_4)(1 + \beta_4)}{\eta_2} = \text{Eup}(e^{x_0}, t) \left[ \frac{(1 + \beta_4)(1 + \beta_4)}{\eta_2 + 1} \right] + \frac{\beta_3 \beta_2 - \beta_3 \beta_4}{\eta_2 + 1} + (\eta_2 - \beta_4)(\eta_2 - \beta_3) \cdot Ke^{-rt} \text{P}^*[S(t) \leq K | S(0) = e^{x_0}] + \frac{Ke^{-rt} \text{P}^*[S(t) \leq K | S(0) = e^{x_0}]}{\eta_2 + 1},
\]

which is exactly (6).

It remains to show that \( A > 0 \) and \( B > 0 \). To do this, we need the following lemma.

**Lemma 3.** For the unique solution \( v_0 \) in Equation (6), we have

\[
K > v_0 + \text{EuP}(v_0, t) = e^{-rt} \text{E}^*\left[ \max(S(t), K) | S(0) = v_0 \right].
\]

**Proof.** We show this by contradiction. First, note that \( v_0 + \text{EuP}(v_0, t) = e^{-rt} \text{E}^*\left[ \max(S(t), K) \right] \) is an increasing function of \( v_0 \). Next, assume by contradiction that \( K \leq v_0 + \text{EuP}(v_0, t) \). Since \( C_\beta - D_\beta = \beta_4 \beta_3 - \eta_2 (1 + \beta_4 + \beta_4) < 0 \), we have

\[
C_\beta K - D_\beta [v_0 + \text{EuP}(v_0, t)] \leq \{C_\beta - D_\beta\} K < (C_\beta - D_\beta) K e^{-rt} \cdot \text{P}^*[S(t) \leq K].
\]

Thus, the left side of (6) would be smaller than the right side of (6), a contradiction. \( \square \)

Now we can show that \( A, B > 0 \). By taking derivative and then using (A6), it is easy to see that the function

\[
C_\beta K - D_\beta [v_0 + \text{EuP}(v_0, t)] - (C_\beta - D_\beta) K e^{-rt} \cdot \text{P}^*[S(t) \leq K] \quad (A7)
\]

is strictly increasing in \( \beta_3 \) and strictly decreasing in \( \beta_4 \). Replacing \( \beta_4 \) by \( \eta_2 \) in (A7) and observing \( \beta_3 < \eta_2 \) and (6), we have \( \beta_3 K - (1 + \beta_4)[v_0 + \text{EuP}(v_0, t)] + Ke^{-rt} \cdot \text{P}^*[S(t) \leq K] > 0 \), yielding \( A > 0 \). Similarly, since \( \beta_4 > \eta_2 \), replacing \( \beta_4 \) by \( \eta_2 \) in (A7) yields \( B > 0 \). \( \square \)

**Appendix B. Proofs for Other Path-Dependent Options**

**B.1. Proof of Theorem 1 for Lookback Options**

**Lemma 4.** We have \( \lim_{y \rightarrow \infty} e^{\text{P}^*[M_X(T) \geq y]} = 0, \forall T \geq 0 \).

**Proof.** It is not difficult to see that the process \( e^{X(t) - G(\theta t), t \geq 0} \) is a martingale for any \( \theta \in (\eta_2, \eta_1) \). Fix an \( \theta \in (1, \eta_1) \) such that \( G(\theta) > 0 \) (such \( \theta \) always exists since \( G(1) = r \geq 0 \)). It follows that \( e^{\text{P}^*[M_X(T) \geq y]} = e^{(1-\theta)y} \cdot e^{G(\theta)T} \cdot e^{\text{P}^*[M_X(T) \geq y]} \cdot e^{G(\theta)T} \). Since \( \tau_y \) is the first passage time of process \( X \) over level \( y \); however, the second term in the previous equation is dominated by

\[
e^{G(\theta)T} \cdot e^{\text{P}^*[M_X(T) \geq y]} \leq e^{G(\theta)T} \cdot e^{\text{P}^*[M_X(T) \geq y]} \cdot e^{G(\theta)T} = e^{G(\theta)T},
\]

where the last equality follows from the optional sampling theorem. Since \( \theta > 1 \), the result follows readily. \( \square \)

Now we are ready to prove Theorem 1. Note that we only need to compute the Laplace transform of \( L(s, M; T) := e^{-rt} \max(M, s e^{M_X(t)}) \) where \( \max(M, s) \) and \( M_X(T) := \max_{0 \leq t \leq T} X(t) \) are constant, and \( M_X(T) := \max_{0 \leq t \leq T} X(t) \). Letting \( z = \log(M/s) \), we have

\[
L(s, M; T) = \text{E}^*[e^{-rT} \max(e^{z}, e^{M_X(T)})] = \text{E}^*[e^{-rT} \max(e^{z}, e^{M_X(T)})] = \text{E}^*[e^{-rT} e^{z} 1_{(M_X(T) > z)}] + ze^{-rT}.
\]

Integration by parts yields

\[
\text{E}^*[e^{-rT} e^{M_X(T)} 1_{(M_X(T) > z)}] = -e^{-rT} \int_{z}^{\infty} e^{y} d\text{P}^*[M_X(T) \geq y]
\]

\[
= -e^{-rT} \left\{ -e^{y} \text{P}^*[M_X(T) \geq y] - \int_{z}^{\infty} \text{P}^*[M_X(T) \geq y] e^{y} dy \right\}
\]

\[
= \text{E}^*[e^{-rT} e^{z} 1_{(M_X(T) > z)}] + e^{-rT} \int_{z}^{\infty} e^{y} \text{P}^*[M_X(T) \geq y] dy;
\]
here we have used Lemma 4. It follows that \( L(s, M; T) = se^{-rT} \int_{0}^{\infty} e^{y} P[y \geq T] dy + Me^{-rT} \). Therefore, for any \( \alpha > 0 \),
\[
\int_{0}^{\infty} e^{-\alpha T} L(s, M; T) dT = s \int_{0}^{\infty} e^{-\alpha T} e^{-rT} \int_{0}^{\infty} e^{y} P[y \geq T] dy dT + \frac{M}{\alpha + r}.
\]
However, it follows from Kou and Wang (2003) that
\[
\int_{0}^{\infty} e^{-(\alpha + r) T} P[y \geq T] dT = A_{1} e^{-\eta_{1} T} + B_{1} e^{-\eta_{2} T},
\]
\[
A_{1} = \frac{1}{\alpha + r} \left( \eta_{1} - \beta_{1,a+a} \right), \quad B_{1} = \frac{1}{\alpha + r} \left( \beta_{2,a+a} - \beta_{1,a+a} \right).
\]
Note that \( \beta_{2,a+a} > \eta_{1} > 1, \beta_{1,a+a} > \beta_{1,a}, = 1 \). Therefore,
\[
\int_{0}^{\infty} e^{-\alpha T} L(s, M; T) dT = sA_{1} e^{-\eta_{1} T} + B_{1} e^{-\eta_{2} T} + \frac{M}{\alpha + r}.
\]
This yields the Laplace transform we obtained in Theorem 1. \( \square \)

**B.2. Proof of Theorem 2 for Barrier Options**

We can write UIC as
\[
\text{UIC} = E^{*}[e^{-rT}(S(T) - K)^{+} 1_{\{S(T) \geq K\}}] = E^{*}[e^{-rT}(S(T) - K)^{+} 1_{\{S(T) \geq K\}}],
\]
\[
-K e^{-rT} P[S(T) \geq K, \text{max}_{0 \leq t \leq T} S(t) \geq H] - I = K e^{-rT} \cdot II \ (\text{say}).
\]

It is easy to compute the second term, as
\[
II = \Psi \left( r + \frac{1}{2} \sigma^{2} - \lambda \xi, \sigma, \lambda, p, \eta_{1}, \eta_{2}, \right.
\]
\[
\log \left( \frac{K}{S(0)} \right), \log \left( \frac{H}{S(0)} \right) \), T). \]

For the first term, we can use a change of numeraire argument. More precisely, introduce a new probability \( \mathbb{P} \) defined as
\[
\frac{d\mathbb{P}}{d\mathbb{P}^{*}}|_{t=T} = e^{-rT} S(T) / S(0) = e^{-rT} e^{X(T)}
\]
\[
= \exp \left( \left( r + \frac{1}{2} \sigma^{2} - \lambda \xi \right) T + \sigma W(T) + \sum_{i=1}^{N(T)} Y_{i} \right).
\]

Note that this is a well-defined probability as \( \mathbb{E}^{*}[e^{-rT}(S(T)/S(0))] = 1 \). We have, by the Girsanov theorem for jump processes, \( W(t) := W(t) - \sigma t \) is a new Brownian motion under \( \mathbb{P} \), and the original process
\[
X(t) = (r + \frac{1}{2} \sigma^{2} - \lambda \xi) t + \sigma W(t) + \sum_{i=1}^{N(T)} Y_{i}
\]
is a new double exponential jump diffusion process with the Poisson process \( N(t) \) having a new rate \( \lambda = \lambda E[e^{\xi}] = \lambda(1 + \xi) \). Now, the jump sizes \( \xi \)'s being i.i.d. with a new density given by
\[
E^{*} e^{y} f_{y}(y) = \frac{1}{E(e^{\xi})} e^{y} \mathbb{E}^{*}[e^{-\eta_{1} Y}] 1_{\{Y \geq 0\}} + \frac{1}{E(e^{\xi})} e^{y} \mathbb{E}^{*}[e^{-\eta_{2} Y}] 1_{\{Y \leq 0\}} + \frac{1}{E(e^{\xi})} \mathbb{E}^{*}[e^{\xi Y}] 1_{\{Y \neq 0\}}.
\]
Thus, \( \beta = p \left( \frac{p \eta_{1}}{\eta_{1} - 1} + \frac{\eta_{2}}{\eta_{1} + 1} \right) \)
\[
= \eta_{1} - 1,
\]
\[
\eta_{2} = \eta_{2} + 1.
\]
In summary, we have
\[
I = S(0) E^{*} \left[ e^{-rT} S(T) / S(0) \cdot 1_{\{S(T) \geq K, \text{max}_{0 \leq t \leq T} S(t) \geq H\}} \right] = S(0) E^{*} \left[ S(T) \geq K, \text{max}_{0 \leq t \leq T} S(t) \geq H \right].
\]
and UIC = \( I - K e^{-rT} \cdot II \), from which the conclusion follows. \( \square \)

**B.3. Proof of Theorem 3 for Perpetual American Options**

**Lemma 5.** Suppose there exist some \( x_{0} < \log K \) and a non-negative \( C^{1} \) function \( u(x) \) such that: (1) the function \( u \) is \( C^{2} \) on \( \mathbb{R} \), and is convex with \( u'(x_{0}) \) and \( u''(x_{0}) \) existing; (2) \( u(x) = -ru(x) = 0 \) for all \( x > x_{0} \); (3) \( u(x) = r(x) < 0 \) for all \( x < x_{0} \); (4) \( u(x) > (K - e^{-T}) \) for all \( x > x_{0} \); (5) \( u(x) = (K - e^{-T}) \) for all \( x \leq x_{0} \); and (6) there exists a random variable \( Z \) with \( E[Z] < \infty \), such that \( e^{-r(\tau \wedge \tau^{*})} u(X(t \wedge \tau \wedge \tau^{*})) \leq Z \), for any \( t \geq 0 \), \( x \) and any stopping time \( \tau \). Here the infinitesimal generator \( D \) is defined in (5). Then the option price \( \Phi(S, 0) = u(\log(S/0)) \) and the optimal stopping time is given by \( \tau^{*} := \inf \{ t \geq 0 : S(t) \leq e^{x_{0}} \} \).
Proof. Define $\tilde{X}(t) = x + X(t)$. Then $\tilde{X}(t)$ has the same generator $\mathcal{L}$. The result now follows from a similar argument in Mordecki (1999, pp. 230–232), except with $M(t)$ being changed to $M(t) := e^{-rt}u(\tilde{X}(t)) - \int_0^t e^{-rt}[-r u(\tilde{X}(s)) + \mathcal{L} u(\tilde{X}(s))] ds$. □

Proof of Theorem 3. Let $x = \log(\nu)$ and $x_0 = \log(\nu_0)$. Then

$$V(x) = \begin{cases} K - e^x, & \text{if } x < x_0 \\ A e^{-\beta_3 x} + Be^{-\beta_4 x}, & \text{if } x \geq x_0, \end{cases}$$

for notation simplicity, we shall write $\beta_3 = \beta_{3,0}$ and $\beta_4 = \beta_{4,0}$. To prove Theorem 3, we only need to check the conditions in Lemma 5. Note that $f(\beta_3) = f(\beta_4) = 0$, and

$$K - e^{x_0} = A e^{-\beta_3 x_0} + B e^{-\beta_4 x_0}, \quad e^{x_0} = A \beta_3 e^{-\beta_3 x_0} + B \beta_4 e^{-\beta_4 x_0},$$

$$0 = K - e^{x_0} \frac{\eta_2}{\eta_2 + 1} - \frac{A \eta_1 e^{-\beta_3 x_0}}{\eta_1 + \beta_3} - B \frac{\eta_2 e^{-\beta_4 x_0}}{\eta_2 + \beta_4}.$$ 

Therefore, Condition 2 follows from Lemma 1 with $h = 0$. Conditions 1, 4, 5, and 6 are trivial by noting that $V(x_0) = V(x_0^-)$ and $0 \leq V(x) \leq K$.

As to Condition 3, note that for $x < x_0$, we have

$$\int_{x_0}^{x} V(x + y) dF(y)$$

$$= \int_{x_0}^{x} (K - e^{y+x}) q \eta_2 e^{y+x} dy + \int_{x_0}^{x} (K - e^{y+x}) p \eta_1 e^{y+x} dy$$

$$+ \int_{x_0}^{x} (A e^{-\beta_3 y} + B e^{-\beta_4 y}) q \eta_2 e^{y+x} dy + \int_{x_0}^{x} (A e^{-\beta_3 y} + B e^{-\beta_4 y}) p \eta_1 e^{y+x} dy$$

$$= K - e^x \left[ \frac{q \eta_2}{\eta_2 + 1} + \frac{p \eta_1}{\eta_1 + 1} \right] - p e^{-\eta_1(x_0-x)} K - \frac{\eta_2 e^{x_0}}{\eta_1 + \beta_3} - A \frac{\eta_1 e^{-\beta_3 x_0}}{\eta_1 + \beta_3} - B \frac{\eta_2 e^{-\beta_4 x_0}}{\eta_2 + \beta_4}.$$ 

Therefore, for $x < x_0$,

$$(-rV + \mathcal{L} V)(x)$$

$$= -\frac{1}{2} \sigma^2 e^{2x} + (\tau - r + \frac{1}{2} \sigma^2 - \lambda x) (e^{-x} - r(K - e^x)) - \lambda(K - e^x)$$

$$+ A \left[ e^{-\beta_3 x_0} \left( \frac{q \eta_2}{\eta_2 + 1} + \frac{p \eta_1}{\eta_1 + 1} \right) - p e^{-\eta_1(x_0-x)} \right] - \frac{\eta_2 e^{x_0}}{\eta_1 + \beta_3} - A \frac{\eta_1 e^{-\beta_3 x_0}}{\eta_1 + \beta_3} - B \frac{\eta_2 e^{-\beta_4 x_0}}{\eta_2 + \beta_4}.$$ 

Rearranging terms and using (3) we have for $x < x_0$,

$$(-rV + \mathcal{L} V)(x) = -rK - e^{-\eta_1(x_0-x)} p \left[ K - \frac{\eta_2 e^{x_0}}{\eta_1 + \beta_3} - A \frac{\eta_1 e^{-\beta_3 x_0}}{\eta_1 + \beta_3} - B \frac{\eta_2 e^{-\beta_4 x_0}}{\eta_2 + \beta_4} \right].$$ 

The right-hand side can be further simplified as

$$K - \frac{\eta_1 e^{x_0}}{\eta_1 + \beta_3} - \frac{A \eta_1 e^{-\beta_3 x_0}}{\eta_1 + \beta_3} - \frac{B \eta_2 e^{-\beta_4 x_0}}{\eta_2 + \beta_4}$$

$$= K - \frac{\eta_1 e^{x_0}}{\eta_1 + \beta_3} - \frac{1}{\eta_1 + \beta_3} \frac{1 + \beta_3}{1 + \beta_4} K - t_0$$

$$- \frac{\eta_1}{\eta_1 + \beta_3} + \frac{1}{\eta_1 + \beta_3} \frac{1 + \beta_3}{1 + \beta_4} K - t_0$$

$$= K - \frac{\beta_3 \beta_4}{(\eta_1 + \beta_3)(\eta_1 + \beta_4)} - t_0 \frac{1}{\eta_1 + \beta_3} (1 + \beta_3)(1 + \beta_4)$$

$$= K - \frac{\beta_3 \beta_4}{(\eta_1 + \beta_3)(\eta_1 + \beta_4)} \frac{1}{\eta_1 + \beta_3} (1 + \beta_3)(1 + \beta_4).$$ 

In summary we have for $x < x_0$,

$$(-rV + \mathcal{L} V)(x)$$

$$= -rK + p \lambda e^{-\eta_1(x_0-x)} K - \frac{\beta_3 \beta_4}{(\eta_1 + \beta_3)(\eta_1 + \beta_4)} (1 + \beta_3)(1 + \beta_4) \eta_1 + \beta_4,$$

from which it is easy to see that $(-rV + \mathcal{L} V)(x)$ is an increasing function, thanks to the assumption $\eta_1 > 1$. Thus, to show Condition 3 it suffices to show that $(-rV + \mathcal{L} V)(x_0^-) \leq 0$. However, since $V(x)$ is bounded and continuous, it follows from the Dominated Convergence Theorem that

$$\mathcal{L} V(x_0^-) = -\mathcal{L} V(x_0)$$

$$= -\frac{1}{2} (V''(x_0^-) - V''(x_0+)) = -\frac{1}{2} (e^{x_0} + \beta_2^2 A e^{-\beta_3 x_0} + \beta_4^2 B e^{-\beta_4 x_0}) \leq 0.$$

But $(-rV + \mathcal{L} V)(x_0^+) = 0$, which completes the proof. □
